ABSTRACT

To analyze the short and long-term outcome of patients aged 65 years and over, after cardiac surgery. Over a 12-year period we analyzed 1750 patients with a mean age of 70.09 ± 3.94 years. They were classified into three age groups: between 65 and 69 (n = 709), between 70 and 74 (n = 695) and 75 years and above (n = 346). Follow-up information was obtained by telephone conversation after a 6-month and 3-year period of discharge from the hospital. Included in the follow-up were 1235 patients and an interview was conducted with 501 (40.6%) patients or their next of kin.

Even though the in-hospital morbidity was highest in the oldest age group, there were no significant differences between groups (p = 0.051). There was no significant difference between groups in the length of hospital stay. The greatest in-hospital mortality was noted in the oldest age group (p = 0.046) compared to patients in the age groups between 65 and 69 and between 70 and 74 years old (p = 0.023 and p = 0.036). In the follow-up study, there was a significantly smaller telephone feedback response in the oldest age group compared to the youngest group (p = 0.003). There were no differences between the groups with respect to mortality and cardiac death after the 6-month and 3-year periods of discharge from hospital.

Our data showed that despite a poor short – and long-term outcome in patients aged 75 and over, all patients had an acceptable operative risk.

Keywords: elderly; outcome; cardiac surgery

INTRODUCTION

According to the Croatian Bureau of Statistics, in the year 2011 there were 4 284 889 citizens in Croatia with a portion of those aged 65 and over at 17.7 % (in 2001 it was at 15.7%) (1). Furthermore, in 2016 there were 4 154 213 citizens in Croatia with a portion of those aged 65 and over increased at 19.6% (2).

From the statistics above, it can be seen that the Croatian population is rapidly aging and is marked by a significantly advanced age. The age index derived from the number of citizens aged 65 years and above in comparison to the age group of 0 – 14 years of age was 116.3 (in 2001 it was 91.9), which means that for the first time in the history of Croatia, in 2011 there were more senior citizens than those of a younger age (1,3).

Longer life expectancy has lead to increased incidence of cardiovascular disease, the primary cause of morbidity and mortality in the elderly. This represents a special challenge for cardiac surgery in the population above 65 years of age. Commonly, cardiac surgery in the elderly is associated with a higher risk of death and longer hospital stay which leads many patients to question the feasibility of such procedures. Contrary to this, advances in anesthetic and surgical techniques, as well as improved perioperative care, have resulted in a significant improvement in

short and long-term outcomes after open heart surgery in the elderly (4,5).

The purpose of this study was to determine the short-term clinical outcome (in-hospital mortality and morbidity) in patients who underwent elective cardiac surgery and were aged 65 years and above. Follow-up information about their long-term outcome was obtained from telephone conversations after a 6-month and 3-year period of discharge from the hospital.

PATIENTS AND METHODS

Over a 12-year period (between January 1998 and December 2009) patients aged 65 years and above, who underwent elective coronary and valve open-heart surgery were included in this retrospective observational study. The computerized database "CardioBase" of the Department of Cardiac Surgery and Transplantation at University Hospital Dubrava Zagreb, was used to identify 1750 consecutive patients. All other types of cardiac surgery, except coronary and valve surgery, were not included in the study such as urgent surgery and revision. The study was compiled in accordance with the Declaration of Helsinki. No specific written consent was acquired for this study since all cardiac surgical patients' data were anonymous.

All patients received standard premedication with morphine in dose of 0.1 mg/kg IM (Morphine Merck®, Merck KGaA, Darmstadt, Germany) and other of their cardiac medications one hour before sur-

gery. Anesthesia induced with midazolam (Dormicum®, F. Hoffman-La Roche Ltd., Basel, Switzerland) 0.1 mg/kg IV, fentanyl (Fentanyl® Janssen Pharmaceutica, Beerse, Belgium) 5-7 µg/kg IV, and pancuronium-bromide (Pavulon®, N.V. Organon, Oss, the Netherlands) 0.1 mg/kg IV. After endotracheal intubation, the lungs were mechanically ventilated using positive pressure (tidal volume 8 mL/kg, ventilatory frequency 12/min) (Cato, Dräger, Lübeck, Germany). Anesthesia was maintained with a nitrous-oxide mixture (60% oxygen and 40% nitrous oxide) and sevoflurane (Sevorane®, Abbott Laboratories S.A., Abbott Park, IL, USA) in doses of 1-1.5 minimal alveolar concentration (MAC). ASA standard monitors were applied and arterial and venous catheters were inserted to measured pressures and cardiac output on admission to the operating room. Moderate hypothermia (32-34 °C) or normothermia was maintained during cardiopulmonary bypass (CPB - heparin-coated circuit) with composition of priming volume: infusol solution 1200 ml (Pliva, Zagreb, Croatia), mannitol 20% 250 ml (Croatian Institute of Transfusion Medicine, Zagreb, Croatia), human albumin 20% 100 ml (Institute of Immunology, Zagreb, Croatia) and heparin sodium 10,000 I.U. (Belupo, Koprivnica, Croatia). Myocardial perfusion during aortic cross clamping (ACC) was obtained by cold blood cardioplegia strategy (a modified Gerald Buckberg solution mixture was a 4:1 oxygenated blood to crystalloid ratio)

to achieve cardiac arrest. Activated clotting time (ACT) was maintained greater than 480 seconds for CPB. Starting dose of heparin 300 units/kg was reversed with protamine sulfate (Fresenius Kabi, Lake Zurich, IL, USA) in a 1 to 1-1.5 ratio. The target mean arterial pressure was 60 mmHg during CPB and 60 – 80 mmHg after CPB. After surgery, patients were transferred to the ICU. Criteria for hospital discharge included hemodynamic and rhythm stability, an afebrile condition with the absence of surgical incision site infection and feeding.

The patients were classified into three cohorts. The first group (n = 709) was between 65 and 69 years old, the second group (n = 695) was between 70 and 74 years old and the third group (n = 346) was aged 75 years and above. The mean age of patients, which included 1201 men and 549 women, was 70.09 ± 3.94 years (range 65 to 87). The mean logistic EuroSCORE of the 1750 patients was 5.42 ± 2.49 (Table 1). The observed parameters were in-hospital morbidity, mortality and length of hospital stay.

Follow-up was conducted through conversation either with the patient or the next of kin by telephone. It was related to the two observed periods: the 6-month and the 3-year period, of discharge from the hospital. A pre-planned questionnaire included the time and cause of death where warranted. The telephone conversations were carried out between March and October of 2017. In the case where there was no answer to the phone calls, a further

two calls were made in the following three weeks. The follow-up study included 1750 patients and an interview was conducted with only 711 (40.6%) patients or the next of kin by telephone.

For data analysis, the SAS System for Windows Release 9.4 software (SAS Institute Inc., Cary, NC, USA) was used. Numerical data were expressed as mean ± standard deviation. Quantitative variables were analyzed for the normality of distribution using the Kolmogorov-Smirnov test. Qualitative data were described by frequencies. To compare the three independent groups, categorical variables were analyzed using the two-tailed Pearson χ^2 test. To compare the three independent groups, continuous variables which were not normally distributed were analyzed using the Kruskal-Wallis test. To find differences between the three groups, we tested the groups in pairs by the Mann-Whitney test corrected for multiple testing. All statistical values were considered significant at $p < 0.05$.

RESULTS

Preoperative and operative data of the study are shown in Table 1. Demographics and preoperative data were similar between three groups except for EuroScore where all three groups mutually significantly differ ($p < 0.001$ for all). Coronary artery bypass grafting (CABG) was performed in 1036 patients. Out of 1036 coronary patients, 476 patients (45.9%)

†comparison between groups with Pearson χ^2 test;

underwent coronary artery bypass grafting without cardiopulmonary bypass (OP-CABG). Valve surgery was performed in 429 patients, and concomitant procedures of CABG and valve surgery in 287 patients. A significantly greater number of patients underwent coronary surgery in the youngest age group in comparison to the other two groups ($p = 0.007$ and $p = 0.001$). The duration of CPB was significantly longer in the oldest age group compared to the youngest group ($p = 0.007$). Although aortic cross clamp time was the longest in the oldest age group, there were no significant differences between groups (Table 1).

There were no significant differences between the groups in terms of prolonged mechanical ventilation, incidence of perioperative myocardial infarction, low cardiac output syndrome, stroke, acute kidney injury (AKI), sepsis and multiple organ dys-

function syndrome. Even though hospital morbidity was greatest in the oldest age group, there were no significant differences between the groups ($p = 0.051$). There was no significant difference between the groups in length of hospital stay. A significantly greater mortality was noted in the oldest age group compared to the other two groups ($p = 0.023$ and $p = 0.036$) (Table 2).

In the follow-up study, a significantly smaller response to the phone interview was noted in the oldest group compared to the youngest age group ($p = 0.003$). There were no differences between the groups with respect to mortality and cardiac death after the 6-month and the 3-year periods of discharge from the hospital (Table 3).

DISCUSSION

According to the Croatian Bureau of Statistics, from 2011 until today, there have been more senior citizens aged 65 years and above than those of a younger age (1,2). Also, today's population in Europe is rapidly ageing. The need for cardiac surgery in elderly patients is rising and a growing number of cardiac patients are presented with coronary heart disease and degenerative valve disease. This is the first retrospective observational report assessing the results of elective cardiac surgery in patients aged 65 and above, categorized into three age groups. Over a 12-year period, from the database, 1750 consecutive patients from 65 to 87 years of age were identified, with the mean age of patients being 70.

Older patients have different cardiac diseases, more comorbidities and are usually referred later for surgery (4). In our study, the youngest age group of patients, between 65 and 69 years old, more commonly suffered from hypertension, while patients between 70 and 74 years of age, more often suffered from diabetes mellitus. The logistic EuroSCORE was used to stratify patients, since it is known to be the most accurate predictor of death in high risk cases (6). It seems to overestimate mortality at lower score levels (EuroSCORE ≤ 6) and underestimate mortality at higher score levels (EuroSCORE > 13) (7). Sündermann et al. (8) report 30-day mortality of 5.5% in 400 cardiac surgical patients ≥ 74 years with EuroSCORE 8.5, while in our the oldest age group mortality was 9.2% with EuroSCORE 6.7 (Table 1 and 2). On the other side, none of prognostic model for predicting mortality in elderly intensive care patients can be currently considered sufficiently valid to be appropriate in our clinical practice (9) (Table 1).

Anesthesiological protocol was the same throughout an operative period. A cardiopulmonary bypass for elective cardiac surgery is instituted with linear flow about 2.5 L/min/m² and myocardial protection was performed using cold blood cardioplegia solution. Patients in the age group of 75 years and above, had a greater in-hospital mortality (9.2%) compared to the other two groups ($p = 0.051$). Some studies show a different incidence of in-hospital mortality in octogenarians undergoing cardiac surgery (from 6.5% to 9.2%) (10,11). The oldest age group of patients was on mechanical ventilation for a longer period of time, but without significance in comparison to the other two groups. Prolonged mechanical ventilation is classified as post-operative ventilation continued for more than 24 hours (12,13). In the same group, there was an increased incidence of perioperative myocardial infarction (4.0%), low cardiac output (2.9%), stroke (3.2%) and acute kidney injury (1.7%), but without significance. Baskett et al. (10) reports

higher incidence of stroke (4.7%) in octogenarians undergoing CABG compared to the age group of 75 years and above. Vives et al. (14) showed a greater incidence of AKI (defined as a rise in serum creatinine >1 mg/dl above baseline) at 2.5% in patients after CABG and at 2.8% after valvular surgery compared to our patients with AKI at 1.5%. Sepsis and multiple organ dysfunction syndrome, as a progressive organ dysfunction in an acutely ill patient, were more common in the oldest age group but without significance in comparison to the other age groups (15,16). This group of patients had one day longer length of hospital stay (18.5 days) compared to the other two groups (Table 2). In another retrospective investigation, Kolh et al. (17) reported an incidence of hospital mortality at 13% in 182 consecutive eighty-year-old patients after cardiac surgery and their length of hospital stay were 18.8 days.

Prospective data on long-term outcome were obtained by telephone conversation with the patient or the nearest kin. Follow-up showed that besides the number of years of life after surgery per se, for the older patients, the quality of life is a second important parameter. There has been no doubt that elderly patients who undergo cardiac surgery have an improvement in their quality of life (18,19). Our follow-up questionnaire had not included questions about symptoms following surgery and other questions about the quality of life, but included two observational periods and causes of death, whether they were of cardiac or noncardiac cause. Overall the patient response to the telephone interview was 40.6% and was significantly smaller in the oldest age group (29.7%). The most common reason for not responding were a change in phone number or address. The total mortality rate of the 711 interviewed patients amounted to 4.1% after the 6-month and 10.8% after the 3-year period of discharge from the hospital. The most common cause of mortality was cardiac death after both observed periods, after 6-months (in 68.9% of cases)

and after 3-years (in 49.3% of cases). Even though the greatest mortality after both the 6-month and 3-year periods of discharge from the hospital was in the oldest age group (7.8% and 14.6%), there were no differences between the groups (Table 3). One retrospective study shows an incidence of long-term survival after three years in the octogenarians undergoing cardiac surgery at 79.1% (15). Previous reports had shown that in spite of a relatively higher morbidity and mortality when compared with younger patients, elderly patients have an acceptable operative risk, and the long-term results are pleasing (20,21). The TIME study presented the greater improvement of quality of life in patients older than 75 who underwent CABG regardless of their greater perioperative risk, compared to those with non-surgical treatment (22).

Even though this study included a large number of patients, limitations of study contain the weakness, inherent to any retrospective study. The study covers an extended period of time which the perioperative management of cardiac surgical patients may have been in some measure changed. In the follow-up study, despite three telephone calls made to every patient, nevertheless there was a poor response rate from the patients to the interview. Furthermore, we did not analyze the actual survival rate after surgery or the quality of life of patients by a questionnaire after hospital discharge, which is something that could be included in a future study, with important implications on long-term outcome. At last, comparison to age-matched population of patients with the same cardiac abnormalities, who were eligible for surgery is a theoretical option, but it would be difficult to perform.

In conclusion, we have confirmed that despite a poor short and long-term outcome in patients aged 75 and over, all patients aged 65 years and above after elective cardiac surgery, have a satisfactory operative risk in our clinical setting.
