Cytomegalovirus (CMV) infection poses risks to newborns, necessitating effective therapies. Given that the damage includes both viral infection of brain cells and immune system-related damage, here we investigate the involvement of cellular prion protein (PrP), which plays vital roles in neuroprotection and immune regulation. Using a murine model, we show the role of PrP in tempering neonatal T cell immunity during CMV infection. PrP-null mice exhibit enhanced viral control through elevated virus-specific CD8 T cell responses, leading to reduced viral titers and pathology. We further unravel the molecular mechanisms by showing CMV-induced upregulation followed by release of PrP via the metalloproteinase ADAM10, impairing CD8 T cell response specifically in neonates. Additionally, we confirm PrP downregulation in human CMV (HCMV)-infected fibroblasts, underscoring the broader relevance of our observations beyond the murine model. Furthermore, our study highlights how PrP, under the stress of viral pathogenesis, reveals its impact on neonatal immune modulation.

With no effective vaccine available<sup>1</sup>, human cytomegalovirus (HCMV) continues to infect approximately 83% of the global population, with prevalence ranging from 60% to 90% in Europe<sup>2</sup>. While primary infection in adults often goes unnoticed, HCMV can invade the fetal brain, resulting in permanent neurological impairments such as mental retardation, vision, and hearing loss<sup>3</sup>. In this regard, HCMV remains the leading cause of congenital infections, affecting approximately 7 out of every 1000 children, occurring during pregnancy or in the first few weeks after birth<sup>4,5</sup>. Regrettably, available antiviral drug options<sup>6</sup> are limited due to potential risks to the developing child, and recent longitudinal cohort studies have revealed that treatments, including ganciclovir and valganciclovir, do not provide enduring benefits<sup>7,8</sup>. To

study congenital CMV disease, we have successfully utilized a perinatal infection model in experimental mice, as HCMV is strictly species-specific<sup>9,10</sup>. While mouse CMV (MCMV) cannot pass the placenta, the brains of newborn mice are developmentally equivalent to 2nd trimester human fetuses<sup>11</sup>. Thus, in the model employed here, we infect newborn mice on day 1 after birth to mimic congenital infection in humans. In this setting, MCMV reaches the brain and causes numerous developmental sequelae reminiscent of those observed in congenitally infected human newborns<sup>12–14</sup>. Most of the damage is believed to be caused by an overreactive immune response, which, while essential for sufficient viral control, can also lead to tissue damage due to excessive inflammation<sup>15</sup>. Accordingly, it has been shown that anti-inflammatory

drugs can reduce abnormalities and alleviate brain damage in infected newborn mice<sup>13,16</sup>. However, the precise underlying factors and contributions that determine the occurrence and severity of damage in this context remain elusive<sup>17</sup>.

Extensively studied due to its devastating role in incurable and transmissible neurodegenerative prion diseases<sup>18,19</sup>, the cellular prion protein (PrP) is a membrane-anchored protein for which recent insights have revealed to serve dual functions in immune privilege: modulating inflammation to prevent immunopathology and directly protecting cells against inflammation-induced damage (reviewed in ref. 20). Notably, PrP is highly expressed in immunologically privileged sites, such as the brain, and its phenotypic effects become evident in the presence of stress and inflammation<sup>21–24</sup>, including viral challenges<sup>25–30</sup>. Studies involving PrP knockout mice (KO) have reported several phenotypes<sup>31</sup>, with some related to immune cell functions (reviewed in refs. 32,33). However, certain functions attributed to PrP based on the analysis of specific KO mouse lines could not be replicated in others<sup>31,34,35</sup>. This discrepancy is primarily due to the influence of *Prnp*-flanking genes in different KO strains. Nevertheless, PrP has been implicated in hematopoietic cell development<sup>36</sup> and binding to/interacting with multiple extracellular and transmembrane ligands<sup>37,38</sup>. It is expressed on the surface of immune cells where it affects their function<sup>32,39–44</sup>, cytokine responses<sup>23,24,45</sup> and immunological synapses<sup>43,46–50</sup>. Additionally, PrP can bind to immune cells, suggesting its interaction with immune receptors<sup>51–53</sup>. With its involvement in various aspects of inflammation and the lack of comparable studies investigating the immunobiology of PrP during the developmental phase of the immune system, particularly in the context of early viral infection, understanding the impact of PrP on congenital HCMV infection requires comprehensive investigation.

To investigate the impact of PrP on the immune system and its potential for immune silencing, we utilized the relatively novel *Prnp*<sup>ZH3/ZH3</sup> mouse strain, a unique and strictly co-isogenic model with C57BL/6J mice, which possesses a specific knockout of the PrP-encoding gene (*Prnp*) without affecting other genes that could potentially influence immune responses<sup>35</sup>. A fraction of PrP molecules is constitutively released (shed) from cells by the metalloprotease ADAM10<sup>54–56</sup>. Our findings identified soluble PrP as a negative regulator of CD8 T-cell response upon MCMV infection, with PrP KO neonates exhibiting increased effector functions of virus-specific CD8 T cells, leading to improved viral control in various organs, including the brain, without significant tissue damage or inflammation. Additionally, we provide a detailed description of the molecular mechanism by which CMV infection causes increased ADAM10-mediated release of PrP from infected cells, a previously unexplored aspect. Interestingly, binding of soluble PrP to CD8 T lymphocytes and the attenuated control of CMV were specific to newborn mice, as no similar observations were documented in adult mice. This study unveils the immune-regulatory function of PrP in congenital CMV infection, shedding light on the molecular and immunological mechanisms underlying viral burden in the developing brain during acute infection.

## Results

### PrP KO neonates exhibit lower MCMV titers attributed to improved control of acute infection by CD8 T cells

In a well-established model aimed at gaining a deeper understanding of brain damage during congenital CMV infection, newborn C57BL/6J mice (WT) are intraperitoneally infected with MCMV<sup>9,10</sup>. To assess the impact of PrP on infection consequences and immune response, we conducted a comparative analysis between WT and *Prnp*<sup>ZH3/ZH3</sup> mice, which are strictly co-isogenic C57BL/6J PrP KO mice that lack only a small portion of the *Prnp* gene, while other flanking genes potentially affecting immune responses remain unaltered<sup>35</sup>. Given that MCMV is detectable in the brain between 7 and 17 days post infection (dpi), with the most significant neurodevelopmental changes occurring between

8 and 10 dpi<sup>14</sup>, we examined virus titers at 8 and 14 dpi (Fig. 1A). Notably, a statistically significant difference in viral titer within the brain was observed on day 14.

Next, we focused on day 14 pi, when the difference in viral titers in the brains of PrP KO and WT neonates was statistically significant. The analysis of other organs also revealed significantly lower MCMV titers in the PrP KO pups on day 14 (Fig. 1B). Again, no significant difference observed on day 8 (Fig. S1A). We concluded that the immunological effects of PrP absence in the context of congenital MCMV infection are not limited to the brain. In contrast, the amounts of virus in adult WT and PrP KO mice, where the virus reaches organs other than the brain, did not show significant differences, leading us to conclude that the effect is specific for neonates (Fig. S1B).

We have shown previously that, in mice infected upon birth, virus peaks in the brain between days 10 and 14 and is undetectable by day 21, congruent with the recruitment of CD8 T cells to the brain<sup>14</sup>. Next, we depleted CD8 T cells to determine whether these cells could account for the observed difference. Depletion of CD8 T cells resulted in an increase in virus titer in the brains of PrP KO mice to a level similar to that measured in WT animals (Fig. 1C). These findings supported the hypothesis of an improved control of MCMV by CD8 T lymphocytes in the absence of PrP. We observed the same in the spleen and liver, indicating that CD8 T cells are indeed the major cause of differences observed between PrP KO and WT mice. In contrast, the differences in the salivary glands were abolished only partially, in accordance with the dependence on CD4 T cells for virus control in the salivary glands<sup>57</sup> (Fig. S1C). We therefore compared CD8 T cell effector functions and observed a stronger capacity of CD8 T cells from PrP KO mice to produce the antiviral cytokines IFN $\gamma$  and TNF $\alpha$  (Fig. 1D, E).

In MCMV infection, CD8 T cells respond to several epitopes, developing virus-specific conventional and inflationary CD8 T cells. The presence of conventional T cells specific for the viral M45 or M57 epitopes indicates the early acute phase of infection, typically occurring between days 10 and 20<sup>14</sup>. Based on the titers observed at 14 dpi, we specifically examined this time-point and observed a significantly higher frequency and number of M45 and M57 tetramer-positive CD8 T cells in PrP KO neonates (Fig. 1F–H). Conversely, no difference was observed in adult mice regarding MCMV-M45 tetramer-positive and MCMV-M57 tetramer-positive CD8 T cells, which correlates with the absence of variation in viral titers (Fig. S1D). The scarcity of CD8 T cells infiltrating WT newborn mice brains during the early days post-infection when infected cells are still detectable by immunohistology (IH) prompted others to use IH for either CD8 T or MCMV detection on a single slide<sup>9,12,14,58,59</sup>. In PrP KO mouse brains, we show CD8 T cell infiltration among infected cells (Fig. 1I left) and a CD8 T cell colocalization with an MCMV-infected cell (Fig. 1I right). However, due to the limited occurrence of such events, we refrain from making quantified comparisons. As another indicator of the enhanced functionality of CD8 T cells derived from MCMV-infected PrP KO mice, we assessed the cytotoxic potential of CD8 T cells by stimulating splenocytes with MCMV-specific peptides. Flow cytometry analysis further confirmed our conclusions, as it revealed an increased expression of CD107a and an enhanced secretion of granzyme B by the PrP KO cells (Fig. S1E).

Collectively, our data indicate the importance of PrP in modulating the CD8 T cell response and influencing viral control during MCMV infection in neonatal mice.

### MCMV-infected PrP KO neonates display a distinct CD8 T cell transcriptome, increased proliferative potential and heightened cytokine production

To gain a deeper understanding of the differences between CD8 T cell populations in PrP KO and WT mice, we employed single-cell RNA sequencing (scRNA-Seq) (Fig. 2A–D).

In uninfected mice, both genotypes were characterized by the presence of cluster O, representing naïve cells expressing the markers

Sell $^+$  (CD62L $^+$ ) and IL7 $^+$  (CD127 $^+$ )<sup>60</sup> (Fig. 2B, C). In MCMV-infected PrP KO mice cluster 1 emerged as the dominant group, represented by the highest number of cells, while cluster 2 prevailed in MCMV-infected WT mice (Fig. 2C, D). Notably, cluster 2 (WT) exhibited the expected profile associated with the effector and contraction phase (CD62L-IL7 $^+$ -KLRG1 $^+$ -CX3CR1 $^+$ ), indicative of short-lived effector cells<sup>61</sup>, while cluster 1 (PrP KO) displayed an intriguing combination of markers (CD62L-IL7 $^+$ -KLRG1-CX3CR1 $^-$ ), deviating from the usual response to MCMV infection<sup>60</sup>. Furthermore, our flow cytometry analysis confirmed the observed differences in marker expression between the

characteristic PrP KO and WT clusters at the protein level (Fig. 2E). Finally, it is worth highlighting the marker KLF2, which is the only one present in the dominant clusters of naïve and WT infected mice (clusters 0 and 2), but not in PrP KO (cluster 1) (Fig. 2B). Considering that this transcription factor is downregulated in effector T cells as a response determined by the affinity of T cell antigen receptor (TCR)<sup>62</sup>, this could speak in favor of a higher efficiency of CD8 T lymphocytes from PrP KO mice to clear MCMV.

The functional role of PrP in antigen-driven interactions with T cells has been observed in various experimental systems (reviewed in

ref. 33). To assess the impact of PrP on the initial antigen presentation, we employed Maxi transgenic mice, which have TCR transgenic CD8 T cells specific for the immunodominant MCMV epitope M38<sub>316-323</sub><sup>63</sup>. Bone marrow was collected from C57BL/6J or PrP KO mice to obtain bone marrow-derived dendritic cells (BMDCs). In vitro comparison of the priming efficiency of infected BMDCs from C57BL/6J and PrP KO mice did not show any notable differences (Fig. 2F), indicating that the observed differences are T cell-intrinsic and not dependent on the priming capacity of antigen-presenting cells. We tested differences in adult (6 weeks) and young Maxi mice (20 days) but did not observe differences in priming via PrP + or - BMDCs in any case. In conclusion, CD8 T lymphocytes in WT and PrP KO mice exhibit distinct transcriptome profiles, and PrP KO mice show improved control of MCMV infection.

#### Clearance of PrP from the surface of infected cells is observed in MCMV and HCMV infections across all analyzed cell types

Although generally considered optimal for studying antigen presentation, BMDCs exhibited relatively low levels of PrP on their surface. During the examination of the dendritic cell line DC2.4 to identify more pronounced membrane expression of PrP, we discovered a striking influence of CMV on surface PrP levels (Fig. 3A). Here, we show that MCMV caused disappearance of PrP from the surface of infected cells. To determine if this regulation is a widespread phenomenon, we initially confirmed it in BALB/c mouse embryonic fibroblasts (MEF) (Fig. 3B). Subsequently, the same downregulation of PrP was observed in MCMV-infected C57BL/6J MEF cells, immortalized NIH/Swiss embryo fibroblasts NIH 3T3, endothelial SVEC4-10 cells, and murine neuroblastoma Neuro-2a (N2a) cells (Fig. 3C). Furthermore, the downregulation of surface PrP was also evident in human foreskin fibroblasts (HFF), primary cells highly susceptible to HCMV infection (Fig. 3D). Building upon these observations, we then turned our attention to unraveling the molecular mechanisms underlying the CMV-induced modulation of PrP levels in infected cells.

PrP is known to be stress-inducible, and our next-generation RNA sequencing dataset<sup>64</sup> fittingly indicated PrP induction upon MCMV infection (Fig. 3E, left). The RT-qPCR data indicated a robust transcriptional upregulation in the early time points (between 3 and 12 h) and sustained induction compared to uninfected cells (between 12 and 30 h post-infection) (Fig. 3E, right). Using flow cytometry and immunoblotting, we indeed observed an increase in total PrP levels at 6 h post-infection (hpi). However, as the infection progressed to 24 hpi, infected cells exhibited significantly reduced PrP levels compared to uninfected controls (Figs. 3F, S2). To unravel the dynamics of PrP at the plasma membrane of infected cells, we conducted surface staining analysis by flow cytometry. Notably, a decline in surface PrP expression was already noticeable at 6 hpi, reaching its lowest level at 24 hpi (Fig. 3G). These results indicate that surface PrP is lost from the plasma membrane under the influence of infection, despite induction at both

transcript and protein levels. Hence, our subsequent focus was to uncover the fate of PrP in MCMV infected cells.

In addition to investigating the dynamics of PrP during MCMV infection, at this point, it was crucial to explore the potential role of PrP in the initial infection of cells (as it could have a significant impact on our in vivo data), potentially leading to weaker infection and lower virus titers in tissues lacking PrP (Figs. 1, 2). To thoroughly explore this aspect, we conducted analyses using MEFs derived from PrP KO mice and N2a cells lacking PrP. Encouragingly, our findings confirmed that MCMV is capable of infecting cells independently of the presence of PrP (Fig. S3).

#### CMV-induced removal of PrP leads extends beyond the cell surface, leading to the progressive loss of cell-associated PrP during the course of infection

To first ensure the reliability of our observations regarding the disappearance of PrP in MCMV-infected cells (Fig. 3), we conducted additional experiments using multiple PrP-directed antibodies, in addition to our in-house-generated antibody to mouse PrP (moPrP.03, Fig. 3F). This comprehensive approach allowed us to strengthen the validity of our findings and to confirm the stark drop of PrP levels in infected cells (Fig. 4A). Furthermore, consistent reductions in PrP amounts were observed in lysates of different cell types upon infection (Fig. 4B) indicating that this phenomenon is not limited to a single cell type. Confocal microscopy analysis further supported our observations, revealing a significant decrease in the abundance of PrP in N2a cells following MCMV infection (Fig. 4C). For HCMV-infected cells, confocal microscopy with human PrP and HCMV markers IE1 or UL56.07 illustrates a clear reduction in PrP expression, confirmed by immunoblot in HFF cells (Figs. 4D and S4). Collectively, these findings show the substantial reduction of PrP in infected cells, prompting further inquiries into the fate and underlying mechanisms governing its removal.

We first examined whether virus-induced loss of PrP occurs through classical cellular protein degradation pathways. However, neither a proteasome inhibitor (lactacystin) nor the lysosomal degradation inhibitor (leupeptin) showed any significant rescue of PrP levels in infected cells (Fig. 4E). To confirm that the loss of PrP in virus-infected cells is not a non-specific phenomenon, we performed a poliovirus receptor (PVR) protein immunoblot in parallel, which showed no loss of PVR (Fig. 4F). Furthermore, to address the possibility that PrP could be hidden/remaining in cell lysate pellets, we utilized a buffer with increased SDS concentration, which confirmed the overall 'loss' of cellular PrP (Fig. 4G). The only cell pathway inhibitor that prevented the loss of PrP caused by MCMV was brefeldin A, which we used as a positive control (Fig. 4H). Brefeldin A, known to inhibit the sorting of newly synthesized proteins, retained newly synthesized PrP within the cell and impaired surface exposure. These findings suggest that mature PrP is not degraded through conventional pathways,

**Fig. 2 | Phenotypic and functional differences of PrP KO CD8 T cells revealed through scRNAseq analysis and functional assays. A–D** scRNAseq analysis of CD8 T cells harvested from spleen tissue of MCMV-infected and naive PrP KO and C57BL/6J mice. leading us to hypothesize that it might be removed by a direct release from the plasma membrane.

### PrP is cleaved (shed) from the cell surface of MCMV-infected cells by the protease ADAM10

Next, we sought to investigate the dynamics of PrP removal from the cell surface in greater detail. We conducted a comparative analysis between the rate of PrP removal from the cell surface (Fig. 5A left) and the rate of removal of PrP protein labeled with antibodies shortly after the onset of infection (Fig. 5A right). In the first case (left), we monitored the classic downregulation of PrP on the surface, reflecting its steady state as observed previously. In the second example (right), however, our focus shifted away from tracking the newly synthesized PrP reaching the surface. Instead, we aimed to understand the fate of PrP already present on the plasma membrane. As anticipated, we observed a notably accelerated removal of PrP already present on the plasma membrane in infected cells (Fig. 5A right). This was further confirmed through confocal microscopy, where the absence of PrP-antibody complexes was observed in infected cells (Fig. 5B). While it is known that PrP-directed antibodies can modulate the internalization of PrP protein<sup>65</sup>, these findings emphasized the need to investigate the underlying mechanisms by which the virus eliminates PrP located on the plasma membrane itself.

Endogenous proteolytic shedding of PrP is performed by the metalloprotease ADAM10<sup>54,55</sup>. Previous studies have shown that HCMV

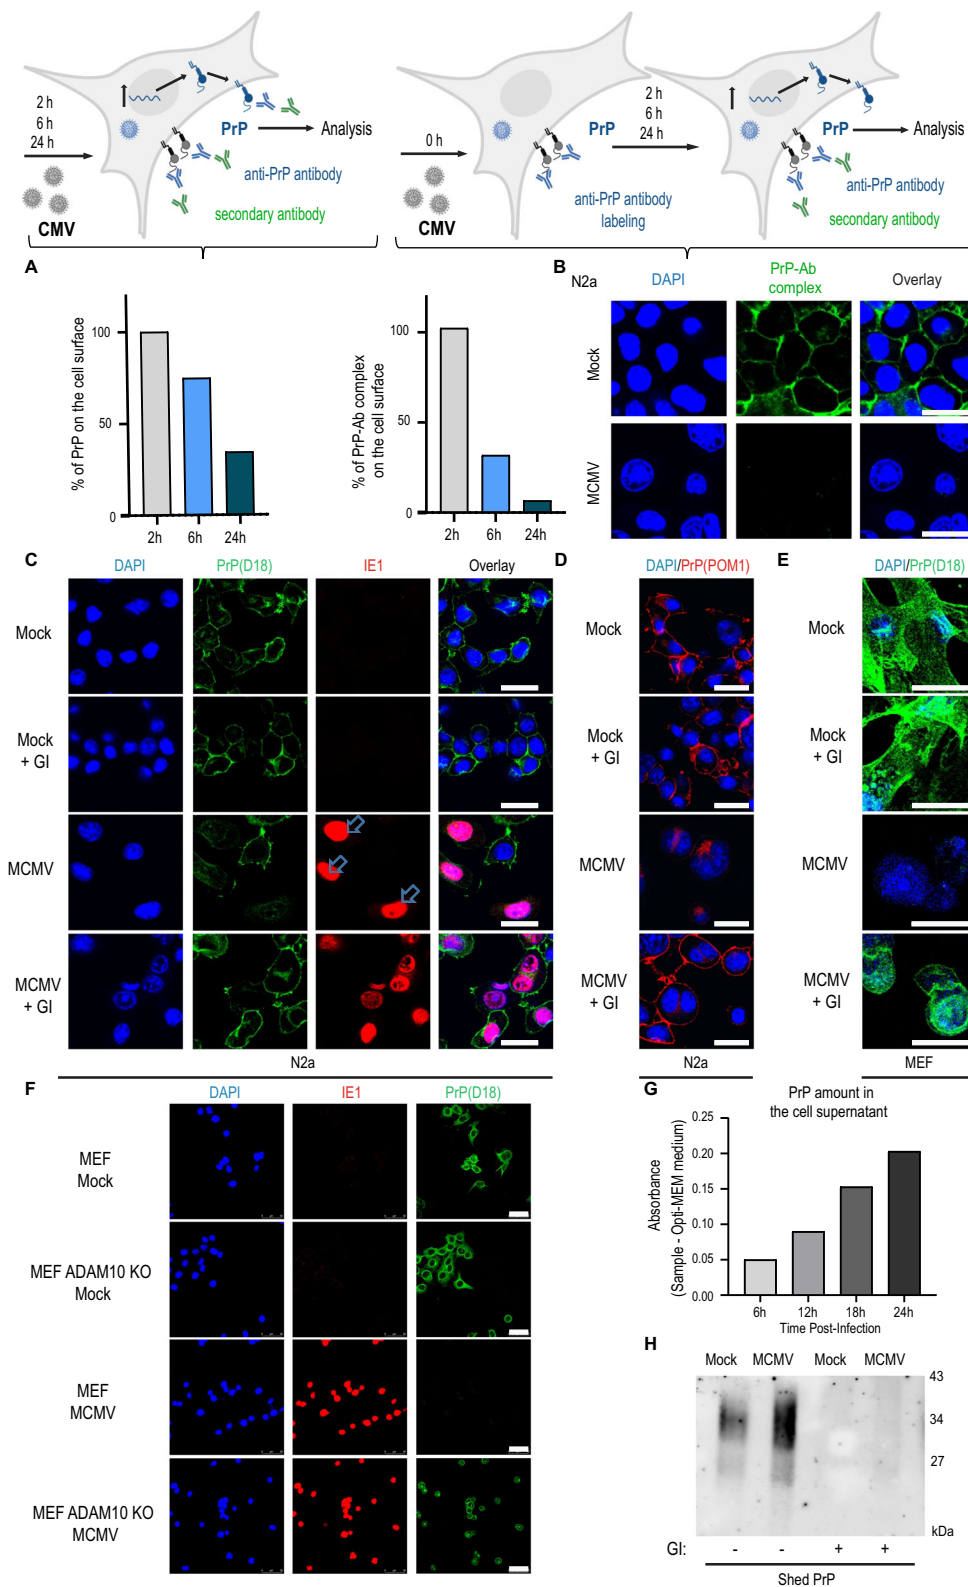

reduces the expression of TIMP3, an endogenous inhibitor of both ADAM10 and ADAM17, resulting in increased ADAM17-mediated cleavage of substrates<sup>66</sup>. To investigate the impact of MCMV on TIMP3 and ADAM10, we reanalyzed a previous RNA-Seq dataset comparing MCMV-infected and mock-infected MEF cells<sup>67</sup>. Only TIMP3 transcripts were significantly downregulated in infected cells (Fig. S5). This confirms that both MCMV and HCMV have the same effect on decreasing TIMP3 RNA expression, which could result in increased activity of ADAM proteases. To further validate the involvement of ADAM10-mediated shedding in PrP removal during CMV infection, we treated N2a cells with the ADAM10 inhibitor GI254023X (GI) prior to MCMV infection. Indeed, GI-treated N2a cells exhibited reduced capacity to remove PrP from the cell surface upon MCMV infection (Fig. 5C, Fig. S6A). We confirmed this finding using an alternative PrP-directed antibody (POM1 instead of D18, Fig. 5D) and by employing a different cell type (MEF instead of N2a, Fig. 5E). Additionally, analysis of ADAM-KO cell line showed that cells lacking ADAM10 exhibited increased PrP levels on infected cells (Fig. 5F, Fig. S6B). Using the mouse prion protein (PRNP) ELISA Kit (abx156832), we confirmed that the amount of PrP gradually started to increase in the supernatants of cells upon MCMV-infection (Fig. 5G). Finally, we employed a cleavage site-specific antibody that exclusively detects the shed form of PrP (sPrP<sup>G227</sup>) cleaved by ADAM10<sup>68</sup> and observed a substantial increase in this fragment in the supernatant of MCMV-infected cells (Fig. 5H). Collectively, our findings provide strong evidence that ADAM10-mediated

**Fig. 4 | MCMV induces selective depletion of mature PrP independent of cellular degradation pathways. A, B** Immunoblots of PrP in mock or MCMV-infected lysates at 24 h post-infection. Different antibodies were used on MEF lysates (**A**) or different cell types were used (**B**). MCMV-M57 and -m04 were used as markers of successful infection. **C** N2a cells, mock- or MCMV-infected, stained for PrP (D18 antibody used). Nuclei visualized with DAPI. **D** Left: Mock-infected HFF cells showed membrane PrP expression (clone huPrP.02), while in HCMV-infected cells, nuclei were stained with anti-IE1 HCMV (clone E13; Argene), with minimal PrP signals. Both cases utilized the huPrP.02 clone and anti-IE1 HCMV (clone E13; Argene), both of IgG1 isotype. Right: Independent analysis showed reduced PrP levels exclusively in HCMV-infected cells, confirmed by UL56.07 antibody recognizing UL56 protein in the nucleus (arrows). Distinct secondary antibodies were employed (anti-IgG1 for huPrP.02 and anti-IgG2b for UL56.07). Nuclei visualized with DAPI.

**E** Immunoblot of mock or MCMV-infected MEF cells grown in the presence of lactacystin (Lac) or leupeptin (Leu) at 24 h p.i. **F** Immunoblot of PrP and PVR in mock- or MCMV-infected MEF cells at 24 h p.i. **G** Immunoblot of PrP in lysates of mock- or MCMV-infected cells at 24 h p.i., prepared with a higher concentration of sodium dodecyl sulfate (SDS). **H** Immunoblot of PrP in mock or MCMV-infected MEF cells at 22 h p.i., grown in the presence of Brefeldin A, which was added 4 hpi and then replenished at 18 hpi. Images (**C**, **D**) were acquired using a Leica TCS SP8 confocal microscope and edited with LAS X software. Scale bars: 50  $\mu$ m (**C**), 10  $\mu$ m (**D**); (**A**–**H**) present typical data illustrating the key observations from the respective experimental conditions, with data being repeated as follows: **A** (2 repetitions); **B** (over 10 repetitions per MoPrP.03/MEF); **C** (3 repetitions); **D** (2 repetitions); **E** (3 repetitions); **F**–**H** (1 repetition).

shedding is an important mechanism by which PrP is removed from the plasma membrane and released into the supernatant of CMV-infected cells.

### Binding of soluble PrP to CD8 T lymphocytes dampens their effector function

Having revealed the initial upregulation and subsequent release of PrP by infected cells, our investigation aimed to explore the potential

relevance of this phenomenon to the enhanced efficiency of PrP KO neonates in eliminating MCMV (Figs. 1, 2). One possible explanation might be that soluble PrP, present in WT neonates, binds to CD8 T lymphocytes and dampens their effector function. To test this hypothesis, we generated a recombinant PrP-Fc fusion protein and exposed it to CD8 T lymphocytes, but observed no binding to CD8 T cells (Fig. 6A, E, in naive mice). Based on these findings, we hypothesized that CD8 T lymphocytes bind PrP protein only in the context

**Fig. 5 | CMV infection triggers shedding of PrP.** Introductory scheme to Fig. 5A, B: (left) classic detection with anti-PrP antibody after the indicated duration of infection. PrP expression is induced, and newly synthesized PrP emerges at the cell surface. All surface PrP found at the chosen time point of infection is detected. (right) PrP labeled with an anti-PrP antibody at 0 h of infection. At certain hours post infection, only previously labeled PrP (PrP-Ab complex) is detected using a secondary antibody. **A** Flow cytometry analysis of surface PrP in MEF cells labeled with the D18 antibody prior to a 2-h, 6-h, or 24-h infection. The data is presented as the percentage of surface PrP relative to the 2 h post-infection time-point (100%). **B** Confocal microscopy of N2a cells labeled with D18 antibody prior to infection, captured 24 hpi. **C–E** N2a and MEF cells mock- or MCMV-infected for 24 h, treated with or without GI254023X (GI), an ADAM10 inhibitor. **C** N2a cells stained with D18 anti-PrP antibody, anti-IE1 MCMV infection marker, and DAPI for nuclei

visualization. **D** N2a cells stained with POM1 anti-PrP antibody, and DAPI. **E** MEF cells stained with D18 anti-PrP antibody, and DAPI. **F** MEF and MEF ADAM10 KO cells mock- or MCMV-infected. 16 hpi cells were stained with D18 anti-PrP antibody, anti-IE1 infection marker, and DAPI. **G** Opti-MEM cell medium was harvested from MCMV-infected MEF cells at the indicated hpi and analyzed using the Mouse Prion Protein (PRNP) ELISA kit (Abbexa). **H** MEF cells were mock- or MCMV-infected and treated with or without GI in Opti-MEM cell medium. Medium was harvested at 20 hpi and subjected to NaDOC/TCA precipitation. Immunoblot performed using anti-shed-PrP antibody (sPrP<sup>G227</sup>). Biological replicates: **A** (2 repetitions for parallel staining); **B** (3); **C** (2); **D**, **E**, **F** (1 repetition each); **G**, **H** (2 repetitions each). **B–E** Leica TCS SP8 confocal microscope, LAS X software. Scale bars: 25  $\mu$ m (**B**, **D**, **E**), 50  $\mu$ m (**F**); NaDOC - Sodium deoxycholate. TCA - Trichloroacetic acid. Scheme created in BioRender.com.

of infection. In support of this, the analysis of PrP engaging with CD8 T cells from newborn mice at 9, 12, and 14 dpi revealed a significant increase in PrP binding compared to CD8 T cells from uninfected mice (Fig. 6A). In contrast, CD4 T lymphocytes and B lymphocytes did not show increased binding to recombinant PrP following infection, thus confirming the CD8 T cell specificity of this phenomenon (Fig. 6B, C).

To assess the impact of PrP binding on CD8 T cells, we incubated splenocytes isolated from infected neonatal WT mice in the presence or absence of recombinant PrP and measured their ability to produce IFN $\gamma$  and TNF $\alpha$ . According to our hypothesis, we expected that PrP binding would inhibit CD8 T lymphocytes, aligning with the stronger activation and improved virus clearance observed in PrP-deficient mice. Encouragingly, CD8 T lymphocytes isolated from MCMV-infected WT mice showed impaired cytokine production in the presence of PrP compared to controls (Fig. 6D). These findings strongly suggest that the CD8 T cell response to MCMV infection in newborn mice can be suppressed through the binding of soluble PrP. To fortify these findings, we showed that CD8 T cell inhibition is dose-dependent on PrP levels (Fig. S7). Furthermore, we demonstrated that binding of recombinant PrP to CD8 T lymphocytes occurs in cells isolated from newborn PrP KO mice infected with MCMV, effectively excluding the possibility of PrP-PrP self-association (Fig. 6E, neonates). Additionally, we confirmed that the binding of recombinant PrP to these PrP-deficient cells reduces their functional capacity (Figs. 6F and S8). This independent confirmation further supports the results presented in Fig. 6D and extends the impact of recombinant PrP on the functional capacity of both WT and PrP-deficient T cells. Consistent with the lack of differences in viral titers among strains, no binding of PrP was observed on adult CD8 T cells from MCMV-infected mice of either genotype (Fig. 6E, adults). Additionally, PrP exhibited no functional effects on non-binding T cells, including those from naïve or adult mice (Fig. S9). To further confirm the impact of PrP on the reduction of the antiviral CD8 T cell response, we adoptively transferred age-matched Maxi MCMV-specific CD8 T cells into MCMV-infected PrP KO or MCMV-infected C57BL/6J neonatal mice. IFN $\gamma$  production by cells transferred to the PrP KO mice, and therefore in a milieu without PrP, was significantly higher compared to the IFN $\gamma$  production by cells transferred to WT mice. Moreover, incubation of CD8 T cells with soluble PrP ex vivo suppressed IFN $\gamma$  production (Fig. S10).

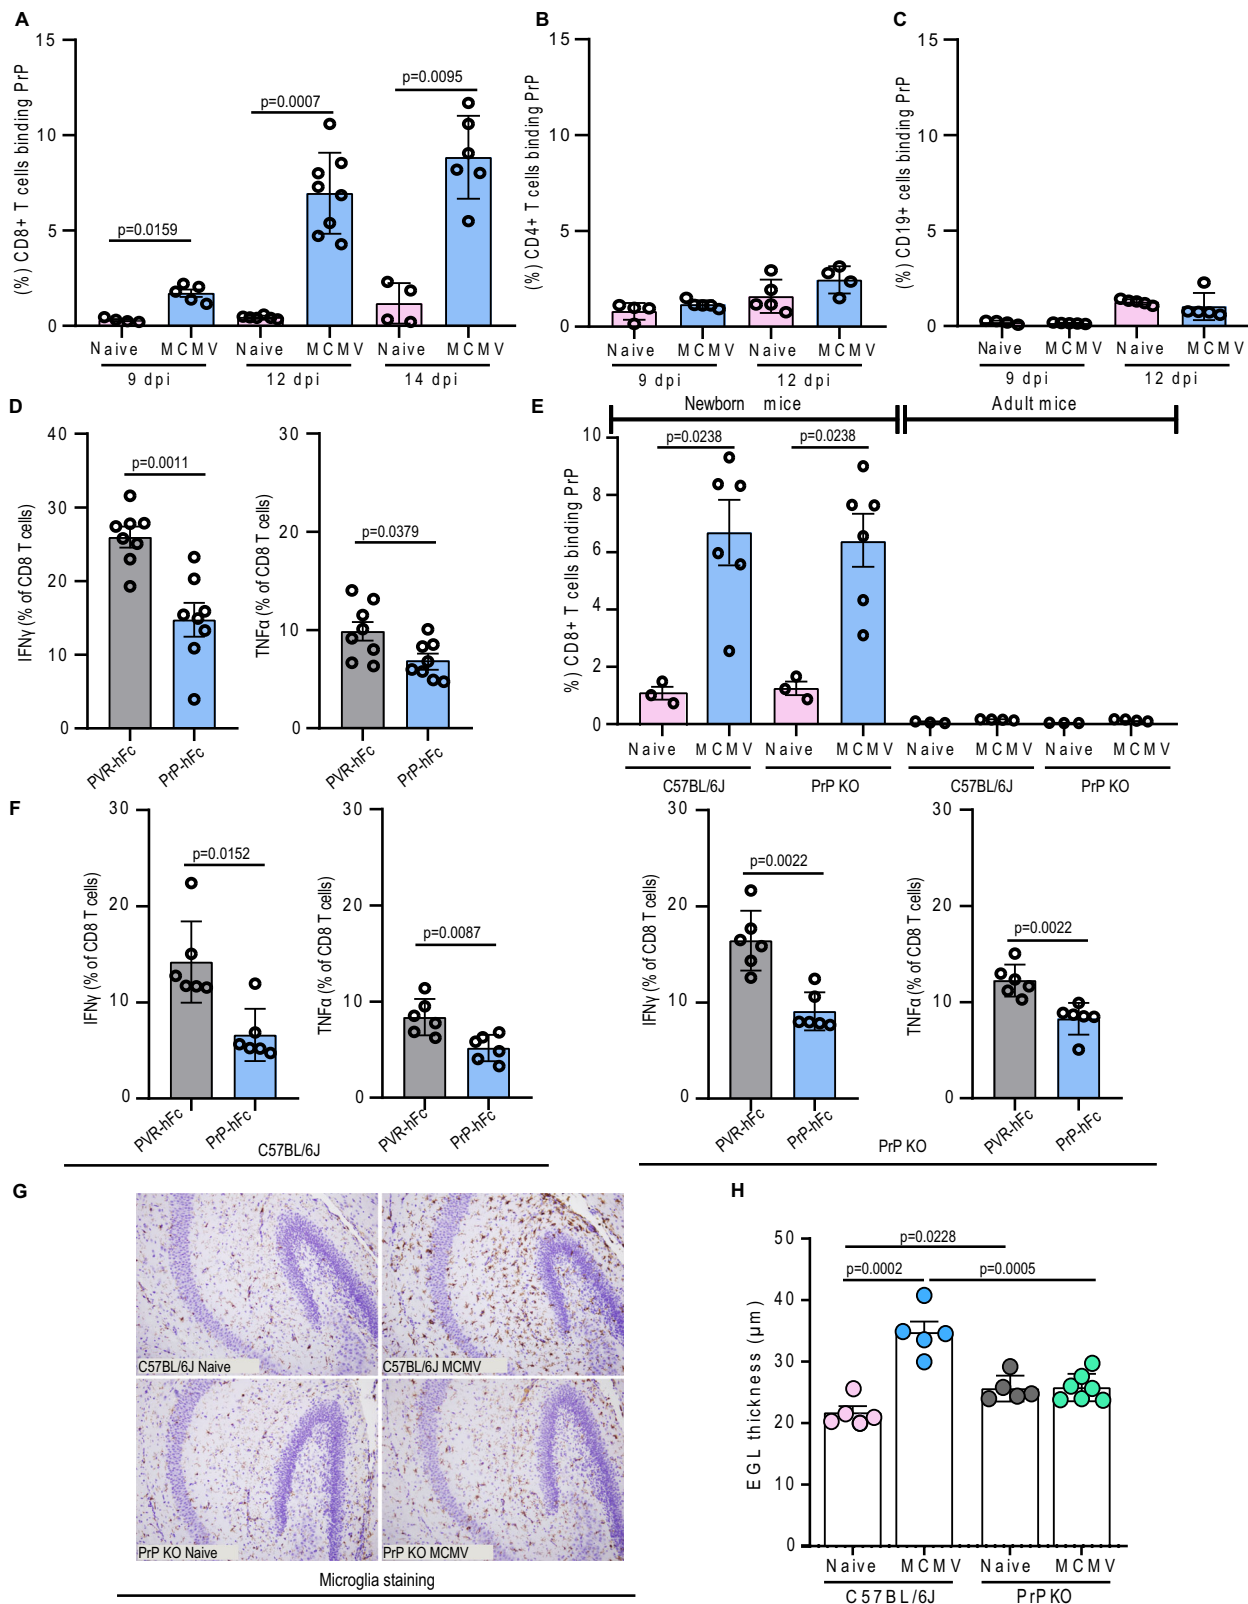

Having established that PrP KO mice show more effective CD8 T cell clearance of the virus, we investigated whether PrP KO mice displayed exacerbated brain pathology due to this enhanced immune response. Histological analyses monitoring typical brain development alterations caused by MCMV infection in WT mice did not reveal similar damage in the brains of PrP KO mice. Notably, in PrP KO mice, we did not observe the typical increase in the number of microglia (Fig. 6G), a contributor to brain damage in CMV infection, nor the characteristic thickening of the cerebellar external granular layer (EGL), both indicating developmental arrest in infected WT mice (Fig. 6H)<sup>10</sup>. The total number of astrocytes, serving as a control, remained similar between genotypes (Fig. S11). Altered morphogenesis

of the brain in MCMV-infected mice, exemplified by a thickened EGL, is marked at earlier days post-infection, up to day 11. Our findings on CD8 T cells binding PrP already at days 9 and 12 (Fig. 6A) were further supported by monitoring the response to viremia in mice at 9 dpi, confirming once again an increased number of virus-specific CD8 T cells in PrP KO mice (Fig. S12). PrP KO mice exhibited a more favorable outcome after brain CMV infection compared to WT, showing better viral control without indications of stronger immunopathology. In conclusion, our results highlight a significant role of PrP in shaping the immune response and pathology during acute viral CMV infection.

## Discussion

HCMV is the most common cause of congenital viral infection, with devastating neurological sequelae resulting from tropism for neural cells<sup>2</sup>. Despite ongoing treatments, children affected by symptomatic congenital HCMV infection still experience poor long-term outcomes<sup>3,7,8</sup>. The extent of damage tends to worsen with age, with the immune system playing a complex and often challenging role in mediating immunopathology instead of controlling the infection and limiting tissue damage<sup>7,13</sup>. Among the immune infiltrates within the brain, virus-specific CD8 T cells play a key role in virus clearance<sup>14</sup>. In our study using MCMV-infected newborn PrP KO mice, we observed significantly lower virus titers in various organs compared to WT mice, a reduction dependent on the presence and activity of CD8 T lymphocytes. Furthermore, we also report that the ex vivo binding of soluble PrP to activated CD8 T lymphocytes reduces their ability to produce IFN $\gamma$  and TNF $\alpha$ . Previous studies have only shown PrP binding to NK cells and monocytes<sup>51,52</sup> but not to T cells. Single-cell RNA sequencing revealed significant differences in the CD8 T cell populations between infected WT and PrP KO neonatal mice. A dominant CD62L-IL7r-klr-klrg1-cx3cr1-klf2- population in PrP KO mice was nearly absent in WT pups. Finally, in vitro experiments showed that MCMV infection significantly upregulates PrP expression, followed by increased shedding of soluble PrP from infected cells via the metalloprotease ADAM10, likely facilitated by virus-mediated downregulation of the endogenous ADAM tissue inhibitor TIMP3. We also observed a similar loss of PrP from the surface of infected cells in our experiments with HCMV.

The interaction between PrP and CD8 T cells appears specific for neonatal mice, as neither this interaction nor improved MCMV control was observed in adult PrP KO mice. Previous studies have shown that neonatal CD8 T cells respond to infection differently than adult CD8 T cells. Neonatal cells exhibit enhanced proliferation, rapid recruitment during infection, a less diverse TCR repertoire, and differences in the expression of surface markers and receptors such as CD127, KLRG1, CD62L, and CD27, even when adoptively co-transferred<sup>69–72</sup>. Additionally, different expression pattern of transcription factors driving effector cell differentiation has revealed several dozen significantly different transcripts<sup>73,74</sup>. In humans, umbilical cord blood T cells express lower amounts of inhibitory

receptors compared to adult peripheral blood T cells<sup>75,76</sup>. There is also a bias towards a Th2 response in human infants and neonates. Mechanisms such as suppression by TGF- $\beta$  and a restricted repertoire of NK cell receptors in neonatal mice help limit inflammatory responses<sup>77,78</sup>, likely supporting colonization with commensals during the postnatal period<sup>79</sup>. In conclusion, a set of regulatory mechanisms is necessary to suppress the immune response early in

life, and neonatal cells express significantly different amounts of numerous transcripts and proteins than their adult counterparts, including those in the surface proteome (reviewed in refs. 73,80). We hypothesize that PrP binding provides an additional layer of T cell regulation in neonatal mice, supporting the developing environment during in utero and postnatal exposure to environmental factors, including intracellular pathogens.

**Fig. 6 | Soluble PrP binding by CD8 T cells from infected newborn mice leads to reduced cytokine production.** **A–C** Frequencies of PrP binding to CD8 T cells, CD4 T cells, and CD19 B cells from splenocytes of naive and congenitally MCMV-infected C57BL/6j mice at indicated days post-infection (dpi); (CD8 T cells – 9 dpi: naive  $n = 4$ , MCMV  $n = 5$ ; 12 dpi: naive  $n = 6$ , MCMV  $n = 8$ ; 14 dpi: naive  $n = 4$ , MCMV  $n = 6$ ; CD4 T cells – 9 dpi: naive  $n = 4$ , MCMV  $n = 5$ ; 12 dpi: naive  $n = 5$ , MCMV  $n = 4$ ; CD19 B cells – 9 dpi: naive  $n = 4$ , MCMV  $n = 5$ ; 12 dpi: naive  $n = 5$ , both groups). **D** Frequencies of IFN $\gamma$  and TNF $\alpha$ -positive CD8 T cells after incubation with PrP (PrP-hFc) or irrelevant protein (PVR-hFc) in the presence of cell stimulation cocktail and protein transport inhibitors. Splenocytes were harvested from congenitally MCMV-infected C57BL/6j mice at 14 dpi ( $n = 8$ ; both groups). **E** Frequencies of PrP binding to CD8 T cells from splenocytes of naive and congenitally MCMV-infected newborn C57BL/6j and PrP KO mice at 14 dpi (left); or naive and MCMV-infected adult C57BL/6j and PrP KO mice at 8 dpi (right) (naive groups:  $n = 3$  each; newborn MCMV:  $n = 6$ ; adult MCMV:

$n = 4$ ). **F** Frequencies of IFN $\gamma$  and TNF $\alpha$ -positive CD8 T cells after incubation with PrP or an irrelevant protein in the presence of cell stimulation cocktail and protein transport inhibitors. Splenocytes were harvested from congenitally MCMV-infected C57BL/6j mice or PrP KO mice at 14 dpi ( $n = 6$ ; all groups). **G** Immunohistochemical staining of microglia (IBA-1) in brains of naive and congenitally MCMV infected mice (**H**) Thickness of the cerebellar external granular layer (EGL) in brains of uninfected and congenitally MCMV-infected C57BL/6j and PrP KO animals harvested at 9 dpi ( $n = 7$  for MCMV PrP KO;  $n = 5$  for other groups). Biological replicates: **A–D** ( $\geq 3$ ), **E** (2), **F** (2), **G** (1) and **H** (2). Values for individual mice are shown. Statistical analysis was performed with GraphPad Prism using the two-tailed Mann–Whitney (U) test (**A–F**) or two-tailed unpaired t-test (**H**). Data on graphs are shown as mean  $\pm$  SEM with  $p$  values indicated. Source data are provided as a Source Data file.

The role of PrP in viral infections has been particularly evident in influenza A infection, as demonstrated by increased pulmonary inflammation and higher viral titers in PrP KO mice<sup>27</sup>. Stimulation of PrP with antibodies induced M2 macrophage polarization, leading to reduced inflammation and viral titer in mice. Herpes simplex virus (HSV), an alpha herpesvirus belonging to the herpesvirus family, has the ability to penetrate the brain, replicate, and occasionally induce an acute inflammatory response. Notably, HSV is the sole herpesvirus that has been investigated in PrP KO mice to date, albeit with inconclusive outcomes<sup>29,81</sup>. However, all of the aforementioned studies have been performed on adult animals. By utilizing our well-established perinatal infection model, we show that the enhanced control of CMV in PrP KO mice is specifically associated with neonatal infection and was absent in adult mice. The underlying processes that are fundamentally different, the reason for the binding of PrP to T lymphocytes following MCMV infection in neonatal mice, and the potential involvement of other immune components still require further investigation.

PrP is released by ADAM10 and soluble PrP has been detected in human and mouse serum, suggesting that it might be of physiological relevance<sup>54,55,68,82</sup>. The processing of PrP is similar across different tissues, and substantial amounts of PrP are released into the medium by splenocytes and cerebellar granule cells<sup>82</sup>. In our study, we observed an increased proteolytic shedding of PrP by MCMV-infected cells, particularly during the initial hours following infection when PrP production was heightened. Notably, astrocytes were identified as a source of soluble PrP in the cerebrospinal fluid during HIV-1 CNS infection<sup>83</sup>. In the follow-up study, it was demonstrated that shedding of PrP can further increase the production of inflammatory mediators, exacerbating HIV-associated brain pathology, and it was suggested that targeting PrP shedding could be a potential therapeutic approach to mitigate the characteristic cognitive impairment observed in neuroAIDS<sup>30</sup>. Among the brain-resident cells, astrocytes represent the predominant cell type infected by HCMV during acute fetal brain infection<sup>84</sup>, making them a potential source of soluble PrP. While quantification in mice is lacking, human plasma PrP levels range from 5 to 10 ng per ml in healthy donors and exhibit a wide range in various disorders, from a few hundred nanograms in sera to several micrograms per ml in cerebrospinal fluid<sup>83,85–87</sup>. To contextualize our chosen PrP concentrations, we referred to a study using a concentration of 10  $\mu$ g/ml for astrocytes *in vitro*<sup>30</sup>. Our experiments utilized 2 or 5 micrograms/sample (reported as 5) with a total volume of 200  $\mu$ l, treating 1,000,000 PBMCs in each sample. Considering PrP-Fc with approximately 1 active site per fusion protein and an estimated molecular weight of around 100 kDa (compared to recombinant PrP's 20 kDa), our calculations indicated an approximate usage of 6.25  $\mu$ g/ml of PrP per 100 times more cells. Importantly, we showed a comparable effect even at 10 times lower PrP concentration (0.5 micrograms of recombinant fusion protein per sample). Acknowledging potential limitations, we recognize that our *in vitro* setup may not perfectly mimic physiological levels. Previous

manuscripts lack discrimination between true shed PrP and overall soluble PrP. Additionally, immune cells within tissues may respond differently, facing hyperconcentration of shed PrP on one side and depletion due to cellular uptake on the other. These considerations underscore the complexity of *in vivo* scenarios.

In our long-standing research, we have investigated various immune ligands regulated by MCMV and HCMV in infected cells. Our established methodology involves identifying the specific viral regulator responsible for the observed effects. To assess the involvement of a specific MCMV gene in PrP regulation, we extensively examined several dozen viral mutants available in our repository, encompassing deletions of nearly all non-essential MCMV genes<sup>88</sup>. Despite this extensive analysis, none of the genes exhibited a specific impact on the surface expression of PrP. However, we did observe that viral mutants lacking the MCMV *m154* gene displayed a relatively weaker effect on the removal of PrP from the cell. It is worth noting that, for our current study, we did not utilize these specific viral mutants due to the broader influence of *m154* on a range of critical ligands involved in antiviral immunity, as previously reported in our own publications<sup>89,90</sup>. Despite the striking PrP loss from infected cells, which was confirmed to be facilitated by ADAM10-mediated shedding during infection, ADAM10 blockade could not completely prevent the reduction of PrP surface levels.

In addition to PrP, ADAM10 plays a role in the cleavage of several crucial molecules, including Notch, PD-L1, ICOS-L, TACI, EGFR/HER-, and NKG2D-ligands<sup>91,92</sup>. Therefore, blocking ADAM10 will, for instance, prevent NK and T cell activation through NKG2D. Based on our findings, simultaneous suppression of PrP shedding is expected to yield a synergistic effect on T cell activation. While targeting ADAM10 activity may appear as an attractive therapeutic strategy, considering its involvement in various cancer types, neurodegenerative diseases, and immune disorders, caution must be exercised due to potential side effects associated with its broad substrate spectrum and wide expression pattern. Given that tested ADAM10 therapies have proven ineffective, multiple factors, including PrP, must be carefully studied<sup>91,92</sup>. Notably, a recent study in Alzheimer's disease models has shown promising beneficial effects of pharmacological ADAM10 stimulation, leading to increased shedding of PrP, a key neuronal receptor for toxic amyloid-beta peptides, from the plasma membrane<sup>93</sup>. It is worth mentioning that CMV is a herpesvirus that, once acquired, establishes lifelong infection characterized by sporadic reactivations. The influence of latent CMV infection on brain pathology is poorly understood<sup>94</sup>, but recent studies strongly suggest a connection between herpesviruses and an elevated risk of neurodegenerative diseases, including Alzheimer's disease<sup>95</sup>.

Numerous PrP-directed antibodies and small molecules have been discovered through research focused on unraveling its devastating role in fatal and transmissible neurodegenerative prion diseases<sup>96</sup>. To further expand our understanding and explore the relevance of our findings, it is crucial to investigate whether PrP or stimulated shedding

can modulate CD8 T lymphocyte responses and whether its depletion can lead to activated CD8 T lymphocytes in other relevant models. Antibodies specifically recognizing shed PrP are already available for rodent models<sup>68</sup>, and efforts are underway to characterize analogous antibodies for the human setting. Moreover, advanced studies are already exploring the specific influence of yet other PrP-directed antibodies and ligands on manipulating PrP shedding in a substrate-specific manner, without affecting the protease ADAM10 or its other substrates in the body. Notably, several PrP antibodies induce increased shedding by binding to the mature protein on the cell surface, while one antibody facilitates rapid uptake and degradation of PrP, effectively eliminating it as a substrate for shedding<sup>65</sup>. These and other means of manipulation<sup>93</sup> should certainly be tested in virus disease models, such as ours, where the removal of PrP from cells is expected to confer benefits without evidence of causing harm, thereby opening up new possibilities for therapeutic interventions.

## Methods

### Mice

Mice were strictly age matched within experiments and handled in accordance with the guidelines contained in the International Guiding Principles for Biomedical Research Involving Animals. All mice were housed and bred under specific pathogen-free conditions at the Central Animal Facility of the Faculty of Medicine, University of Rijeka where they were maintained at 22 °C in a 12-h light–dark cycle, and relative humidity (40–50%). C57BL/6j mice (WT) were obtained from The Jackson Laboratory. Strictly co-isogenic C57BL/6j-Prnp<sup>-/-</sup> mice Prnp<sup>ZH3/ZH3</sup> (PrP KO)<sup>35</sup> were a generous gift from A. Aguzzi. Maxi mice were a generous gift from A. Oxenius<sup>63</sup>. The Ethics Committee at the University of Rijeka and The National Ethics Committee for the Protection of Animals Used for Scientific Purposes (Ministry of Agriculture) approved experiments with laboratory animals (approval number HR-POK-004). Newborn mice were infected as a whole litter intraperitoneally (i.p.) with 400 PFU of MCMV prepared in volume of 50 µl on post-natal day 1. 8–10 weeks old adult male mice were infected with 2 × 10<sup>5</sup> PFU i.p. prepared in 500 µl sterile PBS. Viral titers in organs were determined by standard plaque assay. Virus titers are expressed as PFUs and correspond to the amount of infectious virus per gram tissue or per organ. CD8 T cells were depleted by i.p. injection of 50 µg of anti-CD8 (YTS 169.4, BioXcell) prepared in 50 µl of sterile PBS on days 4, 7, and 10 post infection. To isolate bone marrow to grow bone marrow-derived dendritic cells (BMDCs), 6 weeks old adult female mice were sacrificed, and bone marrow was flushed from tibia and femur. Maxi mice were sacrificed at 3 weeks of age (noted as “young”) and 6 weeks of age (noted as “adult”) for harvesting splenic cells used in the co-cultivation experiments with BMDCs. The investigated research is not influenced by sex. However, sex is consistently taken into account and clearly stated for each analysis involving adult mice. In the case of newborn mice, the analysis was not conducted based on their sex due to their extremely young age (1 day). Since it was necessary to compare mice (uninfected, infected, 2 strains) that were born on the exact same day, selecting one sex was not only deemed unnecessary but also unfeasible. Nevertheless, in an initial large titration experiment, sex was recorded for additional verification, and it was found that sex did not impact virus titer in congenitally infected PrP KO and C57BL/6j at 14 dpi.

### Cells

MEF (mouse embryonic fibroblasts from BALB/c mice, C57BL/6j mice, PrP KO mice, immortalized ADAM10 KO MEF cells and their respective WT controls<sup>97</sup>), N2a (Neuro-2a; murine neuroblastoma cells) SVEC4-10 (a mouse endothelial cell line), NIH 3T3 (mouse embryo fibroblast cell line) and HFF (human foreskin fibroblasts) were cultivated in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% or 3% of fetal calf serum (FCS) and 100 U/ml of penicillin, 100 µg/ml

streptomycin and 2 mM L-glutamine<sup>10,98</sup>. DC2.4 cells (immortalized dendritic cells from C57BL/6 mouse) were cultivated in Roswell Park Memorial Institute (RPMI) 1640 medium supplemented with 10% of FCS and 100 U/ml of penicillin, 100 µg/ml streptomycin and 2 mM L-glutamine. N2a, SVEC4-10, NIH 3T3, and DC2.4 cells are derived from the cell data bank of the Faculty of Medicine University of Rijeka. These are mouse-derived cell lines and the specific sex of the mice from which these cells are derived is generally unknown or unspecified. MEF cells were mixed sex since they were obtained by homogenization of total embryos 17 days after fertilization. BMDC cells were obtained from female mice. Opti-MEM (Reduced Serum Media) was not supplemented. To obtain bone marrow-derived dendritic cells (BMDCs), cells from the bone marrow of C57BL/6 and PrP KO mice were grown for 7 days in 10% RPMI 1640 supplemented with 20% GM-CSF (fresh medium was added every two days into the flasks, 1 ml per 10<sup>6</sup> cells) to obtain BMDCs as a floating and loosely attached fraction of derived cells<sup>99</sup>. All cells were grown in an incubator that enables conditions of 5% CO<sub>2</sub> and 37 °C.

### Viruses

Viruses were produced on BALB/c MEFs using an ultracentrifuge (Sorvall) and titrated by standard plaque assay as described<sup>10</sup>. In brief, virus stocks were titrated by serial 10-fold dilution in 48-well tissue culture plates containing MEF monolayer overlaid with methylcellulose. After incubation for 4 days, plaques were enumerated and plaque forming units (PFU) per milliliter determined. We used the BAC pSM3fr-derived MCMV (C3X), based on the MCMV Smith strain (ATCC VR-1399) as WT,  $\Delta m138$ -MCMV for immunofluorescence assays and  $\Delta m157$ -MCMV for adult mice infection. HCMV strain TB40/E was used for infection of human cells.

### Cell treatment

Cells were seeded (1 × 10<sup>6</sup> cells/10 cm petri dish or 3 × 10<sup>5</sup> cells/6-well plate) and infected with the dose of 0.5–3 PFU/cell. The cells were incubated with virus (30', 37 °C, 5% CO<sub>2</sub>), centrifuged (30', 800 g) and further incubated. Infection of cells in suspension was carried out by resuspending cells in viral suspension (10<sup>7</sup> cells/ml of viral suspension) and incubating (60', 37 °C). Cells were treated with Brefeldin A (5 µg/ml, eBioscience), Leupeptin (15 µg/ml, Sigma-Aldrich, L5793), Lactacystin (10 µM/ml, Sigma-Aldrich, L6785) and GI 254023X in Opti-MEM (3 µM, Merck Millipore). Infection with HCMV was performed as with MCMV, 0.5 PFU/cell for 48–90 h.

### Flow cytometry

Splenic leukocytes were prepared using standard protocols including mechanical dissociation and brief erythrocytes lysis. To isolate lymphocytes from liver, the tissue was mechanically dissociated. A 40% Percoll/liver homogenate suspension was underlaid with 80% Percoll in PBS and centrifuged (25', 1050 g). Fixable Viability Dye coupled to Alexa Fluor 780 was used and Fc receptors were blocked using anti-CD16/CD32 (clone 2.4G2, produced in-house). Flow cytometric analysis included anti-mouse CD45.2 (104, AlexaFluor700 1:100 or eFluor506), CD3 (145-2C11, FITC or SuperBright600 1:100), CD8 $\alpha$  (53-6.7, SuperBright780, 1:400), CD44 (IM7, AlexaFluor700, 1:400), CD19 (eBioID3, PerCP-Cy5.5, 1:800), NK1.1 (PK136, PE-eFluor 610 1:100), CD4 (RM4-5, APC, 1:100), TNF $\alpha$  (MP6-XT22, AlexaFluor488, 1:100 or PE-eFluor610, 1:80), IFN $\gamma$  (XMG1.2, PE or eFluor450, 1:100), KLRG1 (2F1, PE-eFluor610, 1:200 or APC, 1:400), CD62L (MEL-14, PE-Cy7, 1:400) from Thermo Fischer Scientific. Anti-mouse CD8 $\alpha$  (53-6.7, BV786, 1:600) antibody was from BD Biosciences. Gating strategy for tetramer positive populations, cytokine production/cytotoxic potential, PrP binding to cells, and sorting cells for scRNA-seq is included in supplemental information as Supplemental Fig. S13. To measure cytokines, splenocytes cells were incubated in the presence of Brefeldin A (10 mg/ml, eBioscience). Flow cytometry of cell lines was performed

with antibodies D18 or D13 (acquired from H.C.A.; 1:150). The H-2D(b)-MCMV-M45-tetramer and H-2K(b)-MCMV-M57-tetramer were obtained through NIH Tetramer Core Facility (<sup>98S</sup>HGIRNASFI<sub>993</sub> and <sup>816</sup>SCLEFWQRV<sub>824</sub>, respectively). Secondary antibodies included goat  $\alpha$ -human FITC (Jackson ImmunoResearch, 1:100) and rat  $\alpha$ -human IgG Fc PE-Cy7 (BioLegend, 1:200). For PrP detection in HFF cells, we used huPrP.02 clone (1:100) produced in-house. To assess the binding of PrP on CD8 T cells, isolated splenocytes were incubated with 5  $\mu$ g of PrP-hFc fusion protein or an irrelevant fusion protein (produced in-house) for 25 min. Alternatively, cells were incubated for 4 h in the presence of Cell Stimulation Cocktail, along with protein transport inhibitors (eBioscience), added to the cell medium to measure cytokine production in the presence of PrP. Flow cytometry data were acquired using FACSArialu (BD Biosciences) and analyzed using FlowJo v10 (TreeStar) software. The monoclonal antibodies and proteins generated in this study, including anti-human PrP (clone HuPrp.02), and the PrP-long-hFc (hIgG1) fusion protein, have been deposited at the Center for Proteomics, University of Rijeka, Croatia [<https://products.capri.com.hr/>].

### Immunoblot

Cell lysates were prepared using RIPA buffer (NaCl 150 mM, Triton X-100 1%, 0.5% Sodium deoxycholate, 0.1% SDS, 50 mM Tris-HCl pH 8.0; cOmplete™, Mini, EDTA-free Protease Inhibitor Cocktail). 50–100 mg of protein lysate was separated by 12% SDS-PAGE electrophoresis. Incubation with primary antibodies was performed overnight at 4 °C.  $\alpha$ -mouse IgG (1:8000) and  $\alpha$ -rabbit IgG (1:2000) HRP-coupled secondary antibody (Jackson Immuno Research) were incubated at room temperature for 1 h. Supernatants of cells treated with GI 254023X were collected after 5–24 h of infection and precipitated with 0.1% Na-DIC and 10% trichloroacetic acid. Primary antibodies used: MoPrP.03 (1:500), IE1.01 (1:1000), m04.10 (1:1000), M55.01 (1:500), E1.01/CROMA103 (1:1000), mPVR.13 (1:1000) and M57.02 (1:1000) (produced in-house), W226, D18 (1:1000) and sPrP<sup>G227</sup> (1:1000) (acquired from G.L. and H.C.A.). Immunoblot signals were visualized using Image-Quant LAS 4000 mini-instrument (GE Healthcare). Cleavage site-specific antibody for the detection of murine shed PrP (sPrP<sup>G227</sup>) may be provided by Dr. Altmeppen (Hamburg, Germany) upon reasonable request. The monoclonal antibodies generated in this study, including anti-MCMV (clone m04.10, M57.02, IE1.01, E1.01), anti-mouse PrP (clone MoPrp.03), have been deposited at the Center for Proteomics, University of Rijeka, Croatia [<https://products.capri.com.hr/>].

### Immunofluorescence

MEF and N2A cells grown on coverslips were infected with 1–3 PFU/cell of  $\Delta m138$ -MCMV. HFF cells were infected with 0.5 PFU/cell of TB40/E HCMV for 48 h. Cells were fixed and permeabilized in ice cold methanol. Antibodies were incubated for 1 h in humid conditions. Primary antibodies: IE1.01, UL56.07, and HuPrP.02 (produced in-house, 1:100), D18 (acquired from G.L., 1:150), POMI (Millipore, 1:100) to recognize PrP and anti HCMV IE1 (Argene, 1:100). In the antibody internalization assay, cells were incubated with primary antibodies for 20 min in PBS on ice and then washed twice before incubation. DAPI was used to visualize nuclei. The samples were stained with secondary antibodies coupled to fluorescein isothiocyanate (FITC, 1:100) or tetramethylrhodamine (TRITC, 1:100) fluorophores. Cell preparations were imaged using an inverted confocal microscope Leica DM18 (confocal unit: TCS SP8; Leica Microsystems GmbH, Wetzlar, Germany), equipped with UV (diode 405), Ar 488, DPSS 561, and He/Ne 633 lasers, and with 4 detectors (2  $\times$  PMT and 2  $\times$  HyD). An HC PLAPO CS2 (63 $\times$ /1.40 oil) oil immersion objective was used. Images (515  $\times$  515 pixels) were acquired using LAS (Leica Application Suite)  $\times$  software (Leica Application Suite  $\times$  3.5.6.21594), in sequential mode, with pixel sizes ranging from 481.47  $\times$  481.47 nm to 120.37  $\times$  120.37 nm. Each

experiment was acquired under the same parameters, referencing control preparations. Adjustments included minimal thresholding consistently applied to all samples within the same group. No gamma correction, pseudocoloring, contrast adjustment, or similar modifications were applied. The monoclonal antibodies generated in this study, including anti-HCMV (clone UL56.07) and anti-human PrP (clone HuPrp.02), have been deposited at the Center for Proteomics, University of Rijeka, Croatia [<https://products.capri.com.hr/>].

### Histology

For morphometric analyzes of cerebellum, serial sagittal sections (3  $\mu$ m thick) were stained with cresyl violet (Thickness of the cerebellar EGL was measured at eight points along the primary cerebellar fissure). Immunohistochemical staining was performed using anti-mouse Iba-1 antibody for microglia (FUJIFILM; Wako Chemicals) and GFAP for astrocytes. Antibody binding was visualized with peroxidase-conjugated goat anti-rabbit IgG antibody (Abcam), followed with 3,3'-diaminobenzidine (Dako). Slides were counterstained with hematoxylin. The liver staining was performed with hematoxylin and eosin. Histological slides were analyzed with BX 51 microscope (Olympus) and CellSens Dimension software were used (cellSens Standard V1.14).

### qPCR

RNA was extracted from N2A cells using an RNA extraction kit (NucleoSpin RNA Plus; MN), and cDNA was generated with a reverse transcription kit (iScript Reverse Transcription Supermix for RT-qPCR; BioRad). The expression of mRNA was examined by qPCR with a 7500 Fast Real Time PCR machine 7500 software (v2.3) (ABI). TaqMan assays were used to quantify the expression of Prnp (Mm00448389\_m1). Relative mRNA expression was normalized by quantification of Gapdh (Mm05724508\_g1) RNA in each sample.

### ELISA

MEF cells were seeded in a 6-well plate and infected as described in the Cell treatment section. Supernatants were harvested from MCMV-infected cells at 6, 12, 18, and 24 h post-infection (from independent wells). Cells were grown in Opti-MEM medium (Thermo Fisher). The Mouse Prion Protein (PRNP) ELISA Kit (Abxexa, abx156832) was used to measure the absorbance in samples, with the Opti-MEM absorbance subtracted as a blank. The absorbance was measured using a TriStar LB 941 multimode microplate reader (Berthold) with the wavelength set at 450 nm and MikroWin2010 software (v5.24).

### Statistical analysis

Data are presented as mean or mean  $\pm$  SEM. Statistical significance was determined by either two-tailed Mann–Whitney U test or two-tailed unpaired t-test using GraphPad Prism v8. A value of  $p > 0.05$  was deemed not statistically significant, if significant  $p$  value is denoted in the figure. Differences between values were considered significant when \* $p < 0.05$ , \*\* $p < 0.01$ , \*\*\* $p < 0.001$ , \*\*\*\* $p < 0.0001$ . In the figure legends, detailed information is provided regarding the experimental design, including the number of replicates for each experiment, the number of animals per group, and other relevant data.

### Single cell RNA-sequencing

Splenic leukocytes were prepared from congenitally MCMV infected and naïve PrP KO and C57BL/6j mice 14 days post-infection using standard protocols including mechanical dissociation and brief erythrocyte lysis. Cells were counted and cryopreserved in fetal bovine serum (FBS) supplemented with 10% DMSO at  $-80$  °C. Gently thawed samples were stained with Fixable Viability Dye (FVD) and fluorochrome-conjugated antibodies and two target populations were FACS sorted by MoFlo EQ Astrios (Beckman Coulter): FVD<sup>CD45.2</sup><sup>+</sup>CD3<sup>+</sup>CD19<sup>+</sup>CD8<sup>+</sup> T cells and FVD<sup>CD45.2</sup><sup>+</sup>CD3<sup>+</sup>CD19<sup>+</sup>NK1.1<sup>+</sup> NK cells.

For single-cell RNA-seq experiments, the Chromium Next GEM Single Cell 3' v3.1 kit (10X Genomics) was used according to manufacturer instructions. Each sample was composed of 10,000 freshly sorted T and NK cells in a ratio of 9:1, respectively. Briefly, the single-cell suspension was loaded on the 10X Chromium controller to generate the Gel bead-in Emulsion (GEM). After the encapsulation, cells were lysed, and the barcoded mRNA was reverse-transcribed. The generated cDNA was amplified and used to prepare libraries for next-generation sequencing (NGS). The sequencing was performed on a Novaseq S4 (Illumina) sequencer aiming at 20k reads/cell.

### Sequences and data processing

Genome mapping and count matrix generation were done following 10X Genomics Cell Ranger pipeline (v6.0.1) with the refdata-gex-mm10-2020-A reference genome. scRNA-seq datasets were processed using Seurat V3 (<https://satijalab.org/seurat/>) in R (R Core Team (2022)). R: A language and environment for statistical computing. R Foundation for Statistical Computing, Vienna, Austria. URL <https://www.R-project.org/>. Cells with more than 10% of mitochondrial gene fraction, less than 500 detected genes, and less than 1000 UMI were discarded. Based on marker genes expression and singleR annotation, cells not corresponding to either NK or T-cells were also discarded. Normalization was performed using the SCTransform Seurat function with 2500 variable features and a regression on the mitochondrial fraction. UMAP generation and clustering were performed following Seurat workflow with the first 30 PC. All 5 samples were merged using the Seurat merge function. The 2 replicates (PrP-KO-MCMV) overlapped completely, suggesting that no corrections or data integrations was required.

### Graphics

BioRender was used to create the respective images, with the licenses provided as follows: Fig. 5a, b: Agreement Number: ZN272VJ45S; Graphical Abstract: Agreement Number: CG272VK2TH.

Additionally, all graphs were generated in GraphPad Prism (v8), then exported and imported into Adobe Illustrator CS5 for panel organization and font adjustment.

### Reporting summary

Further information on research design is available in the Nature Portfolio Reporting Summary linked to this article.

### Data availability

Single-cell RNA sequencing (scRNA-seq) data generated in this study have been deposited in the NCBI Gene Expression Omnibus (GEO) archive platform database under accession code [GSE245338](https://www.ncbi.nlm.nih.gov/geo/query/acc.cgi?acc=GSE245338). The data source file, containing raw data of ex vivo experiments and uncropped Western blots, is in Excel format and available at <https://doi.org/10.6084/m9.figshare.24290398.v2>. Source data are provided with this paper.

### Code availability

The R scripts used for the scRNA-seq analysis will be available in public repositories by the end of 2024 as part of the Institut Pasteur's joint script deposition. Until then, the scripts are available upon request from Sébastien Mella ([sebastien.mella@pasteur.fr](mailto:sebastien.mella@pasteur.fr)) or the corresponding author.

## Acknowledgements

We would like to express our gratitude to S. Malić and K. Miklič for their invaluable assistance in laboratory analyses. Additionally, we extend our appreciation to T. Rudančić, E. Ražić, D. Rumora, and L. Mikša for their excellent support throughout the project. We thank Paul Saftig (Kiel, Germany) for ADAM10 KO (and respective WT) MEFs. We also thank A. Aguzzi (Zürich, Switzerland) and A. Oxenius (Zürich, Switzerland) for generously providing *Prnp<sup>ZH3/ZH3</sup>* and *Maxi* mice, respectively. This research has been supported by: Croatian Science Foundation grant IP-2020-02-6617 (T.L.R.) University of Rijeka, uniri-biomed-18-233 (T.L.R.) University of Rijeka, uniri-iskusni-biomed-23-197 (T.L.R.) University of Rijeka, uniri-biomed-18-205 (S.J.) “Strengthening the capacity of Cer-VirVac for research in virus immunology and vaccinology”, KK.01.1.1.01.0006, awarded to the Scientific Centre of Excellence for Virus Immunology and Vaccines and cofinanced by the European Regional Development Fund (S.J.). Croatian French program Cogito partnership Hubert Curien (T.L.R., M.H.).

## Author contributions

Conceptualization, T.L.R., S.J., and D. Karner.; Investigation, validation and formal analysis, T.L.R., D. Karner, D. Kvestak, P.K.B., M.C.B., B.L., I.B., V.J.L., M.G., J.T., A.K. M.H., E.K., V.L., S.M., G.L., and H.A.; Funding acquisition and project administration, T.L.R., S.J., and M.H.; Writing, T.L.R., S.J., D. Karner, M.H., G.L., and H.A.

## Competing interests

The authors declare no competing interests.

## Declaration of Generative AI and AI-assisted technologies in the writing process

During the preparation of some parts [Introduction, Results, Discussion] of this manuscript, the authors used ChatGPT to improve the readability of the manuscript. After using this tool, the authors reviewed and edited the content as needed and take full responsibility for the content of the publication.

## Ethics

The Ethics Committee at the University of Rijeka and The National Ethics Committee for the Protection of Animals Used for Scientific Purposes (Ministry of Agriculture) approved experiments with laboratory animals (approval number HR-POK-004).
